1. Introduction

Early hypertext with preset buttons whether determined algorithmically or by human intervention needs to be upgrades to be useful for law with provision for dynamic links to be make in context at run time. The current state of the art [Nielsen 1990] is to use dynamic frames but these are more to do with formatting displays rather than for connecting and identifying relevant content. The hypertext markup to related material elsewhere on the Web [Manager 1995] but the user has to provide the means for identifying the material.

However, users need be assured of the quality of their legal information system. The quality controller like in any industrial process has to be at a separate supervisory level. This is a trigger mechanism in the system to identify relevant information in context and is also a self awareness where the information checks itself for completeness and its own limitations. Intelligent hypertext is an initial step at this level but intelligence is insufficient without a layer of consciousness. The quality assurance level is a closure over all participating sub-systems, whether local to the end-user or global and belonging to the information providers.

The information in the subsystems may come in any form or format. Of great importance for law is the image data found in multimedia for the large quantities of documents that are being input by scanners in legal case [Chepalis 1994]. A hypertext system that cannot search, identify and retrieve the contents of documents held as image bits has little value for lawyers. A move in this direction to provide features for heterogeneous data can be seen in systems like HyperNet [Marovac & Osburn 1992].

Without proper procedures, the less paper office can result in a loss of integrity. To ensure consistency, some formal model is needed to underpin the interoperable subsystems [Heather & Rossiter (in press)]. As information systems are real-world and open, the models need to be drawn from con-
structive mathematics [Heather & Rossiter 1994] where intuitionistic logic seems to be able to give a high formalism to common sense reasoning and experience.

As legal information systems become larger and more complicated it is very easy for the user to get lost in them. Even intelligent hypertext becomes inadequate. It can provide the user with a non-linear connectivity but to be of value the system needs to know where the user is, where the user has come from and where the user is going, all relative to the contents of the information at any point.

2. Types of Awareness

But the system also needs to provide of awareness feature. There is the nature of the information relative to the informational needs of the user and incidentals like the appropriate methods of displaying the data relative to the users individual preferences. More important is the self-awareness of the information relative to information elsewhere, for example to a source of continuous updates. Otherwise, hypertext can misinform.

Whether computer will in the future exhibit the characteristics of human consciousness is an interesting subject of speculation. Of more current importance is the need for information systems to have a current awareness of the contextivity of the information that is available. This encompasses both local disks, CD ROM, etc. under the user’s physical control as well as the interaction of these with any central on-line facilities over which the user has electronic control at least as far as access and availability.

Even with the old printed medium there were and still are various levels of information providers and information users. At one end, there is the consciousness that a book seller has of the availability of information extending little beyond a stock of items currently in market demand or potential demand together with a list of titles and authors that can be ordered. Unless specialized, the bookseller’s awareness will not normally extend beyond books in print. There are librarians who have more regard for the content of the information. This information goes beyond books currently in print and includes the use of bibliographies.

A reference librarian on the other hand has more interaction with the contents of the information. That is the librarian actually opens the books in question. At the other extreme is the lawyer whose function is to dispense the information in the form of advice involving construction and
application of legal source documents to clients who may never actually see the books themselves or even know that they exist. The lawyer has to have an appreciation of knowing what exists and how to find it. Because of the volume and complexity of the information available, the awareness carried around in the lawyer’s head is only how to go about finding some relevant piece of information and not any particular source. It is the sophisticated aim to make conscious reasoned connections that legal hypertext must address.

2.1. Conscious Reasoning as Connections

Legal reasoning lies at the heart of the practice of Law implicit in routine procedures and explicit in activities like legal research, legal information retrieval and legal decision making.

Each age has its own view of logic and the application of logic in the wider concept of reasoning. Reasoning today is making connections: making connections between different categories of objects which may be mixed abstract and concrete. To reason is to impose a structure on the objects. This order may be one of many possible. There may be a unique path but in the law there is usually not just one way to reach the same conclusion and sometimes there may be equally valid paths to other conclusions. In terms of discrete mathematics the ordering is to identify relationships between objects.

Whether the objects and relationships are considered separately or wrapped-up together is a matter of viewpoint. The Anglo-Saxon word *thoughts* express this dichotomy perhaps even better that the word *reasoning*. Comparable perceptions are to be found in other modern relevant topics such as the object-oriented paradigm and connectionist models like parallelism and neural nets.

The older concept of the continuum has been displaced by discrete objects partly because of strong digital influence from computer science and partly arising from a better understanding of physical processes.

A critical feature in this reasoning is the connections that pass through real-world events. This provides a source of variety and normally determines that to particular path is fixed for all time.

2.2. Hypertext Connections Need to Reflect Real-world Links

Interferences in making the right on pragmatic considerations which may be very subject to the peculiarities of the situation or there may be a
more generalizable context sensitivity. Take a legal question which illustrates this by relying on economic circumstances.

Who pays a higher rent: tenants of controlled or uncontrolled tenancies?

Controlled tenancies are connected to security of tenure so that tenants subject to a controlled tenancy have security of tenure whereas the uncontrolled do not have the same security. As security is more valuable, the first impressions might be that controlled tenants will pay more for the tenancy if secured. In practice, secure tenants on average pay much less than unsecured tenants. It is a matter of making the right connections. Controlled tenancies also have their rents regulated so that they cannot be increased. The real-world situations that need to be connected are that because of the demand for housing, those who cannot obtain controlled tenancies have to take tenancies where is no control over the rent charged.

This is a kind of context sensitivity that shapes the result that uncontrolled tenants pay more. This could be determined by reference to statistical data of mean rents for the different types of regulated property, however, a few moments reflection will show that non empirical knowledge is needed. The correct conclusions can be made by making the right connections. Again, these connections are the only ones that could be made, namely that controlled tenancies only exist in times of shortage for otherwise market forces will keep the rents low.

What form of mapping do the relationships take? Essentially it would seem that they depend on some kind of pattern matching. At the simpler level, it is the identification as in the sequence of characters in connections made through vocabulary. Higher order connections can be made at a very abstract level as in a pattern of legal objects and events or facts which by induction make a new legal object and which can by a connection of transference amount to a reasoning by analogy. It is the basis of hyperspace navigation that to low-level connections and the high-level reasoning processes are essentially equivalent classes. The question of the practical technology is how to handle these objects and their identities. This is a class of problem relevant to any implementable information system, that is knowledge base, deductive databases, advanced expert systems, as well as hypertext.

The connections are made in a coordinate space which is not cartesian and where the points are objects of some complexity. A human being is a good example of a complex object consisting of a bundle of characteristics with a unique identification. External positions change with time. Internal characteristics depend on time and also on external positions.
3. LAW AS STRUCTURE OF IDENTIFIABLE OBJECTS AND RELATIONSHIPS

3.1. Objects and Subobjects

What are the legal objects? They appear to be recursive structures that can be analyzed in various ways as, in common law jurisdictions, principles, norms concepts, authority, precedents, ratio decidendi, obiter dicta, primary and secondary rules, duties, obligations, responsibilities, rights. There are finer distinctions, for instance between the fiduciary duty of a trustee and that of an agent. Common law cases are very full instances of legal objects forming nodes in a network approximating to a Boolean lattice of citations or some more complicated partially-ordered set of a non-linear chain of inference. While the document is an object, it is also composed of many interesting concepts that may be legal objects in their own right. The document is an aggregation of those subobjects where it has to be noted that the position of a document in the network normally depends on the connections between the subobjects. A single document may be a member of quite different networks because of quite disparate subjects.

The primary sources of the common law of England at present consist of highly structured documents, cases and statutes inter-locked together [Rossiter, Sillitoe & Heather 1990] by the subobjects they contain. These are the principles concepts and arguments that have to be connected to arrive at the conclusion to resolve a legal problem. In order to represent readily the complex relations, both statutes and case reports employ an elaborate presentation of text with diverse formats and multiple character sets and sizes. To capture adequately the detailed structure of the relationships embedded in this text, sophisticated modeling techniques are required to retain the information and transform it to a machine representation.

Database techniques can provide in electronic publishing the typing corresponding to typography. The printed version presents a fixed view of the structure which has to be accepted in a common form by all readers although different views will be in their minds as they read the text. The organization of the text data as appropriate for different users, however is now available by exploiting the power of computers for logical re-organization. By holding the complete structure of each statute and case in database records, for example, the display format can be readily changed to meet new circumstances: presentation of output to the human eye require quite different forms from operation in a machine-machine mode where the output is directly into a word-processor or mark-up language [Heather 1989], or where one machine interrogates another for information [Connolly 1985].
3.2. Connections in the Law

Hyperspace is equivalent to a multimedia database composed of the complex objects described above in contrast to traditional types of data. Database for simple data developed out of advances file handling and it was soon realised that it was necessary to identify the kind of relationship which existed between data. The traditional structures are the network, hierarchical and the relational model of Codd. With networks based on the theory of directed graphs, the hierarchical on nested trees and the relational model relying on mathematical sets, these are still only lean representations of relationships in the real world.

Semantic models have developed to meet the need to specify information about the kind of relationships like the way the relational model was extended in Codd’s Tasmanian model RM/T [Codd 1979] to capture more meaning through the introductions of rules of relationships and integrity. The most popular of the semantic models is probably the E-R model of Chen but this has been extended in different ways to suit different users [Spaccapietra 1987].

For instance the type and attribute form had to be added to Chen’s original style of representation and Sakai added generalization. The important deficiency of manipulation and the specification of behavioural characteristics has been satisfied in later models by Taxis, Event and SHM+. The complex nature of the objects on the other hand has been satisfied by the development of object-oriented models such as the Semantic Association Model SAM for use in statistical database.

They show the way and some of these models have already been applied to document structures for example E-R [Heather & Rossiter 1987], [Heather & Rossiter 1988], extended relational and Taxis [Heather & Rossiter 1989], and object-oriented and SQL, relational [Heather & Rossiter 1990]. None of the models have all the necessary features. The kinds of relationships needed are:

- abstractions such as aggregation, generalization, specialization, inheritance, classification, definition, designation, association;
- structural such as models, nets, tables, hierarchies, entity classes, E-relations, F-relations;
- statistical such as summation, averages, probabilistic, fuzzy;
- ordering such as sequence, Markov chain, probabilistic, temporal, stochastic;
- reductionist such as projection, parallax, derivation, view;
- behavioural such as dynamic, functional, transaction, operational;
• synthetic such as composition, join, union, cross-product, combined, concatenation, insertion, injection, embedded, tributary;
• analytic such as selection, intersection, adjacency, parametric, attribution;
• parallel such as synchronization, collaborative, collateral, adjacency, adjoin, redundant, orthogonal, anti-parallel, contributory.

Database technology has made progress with some but not all of the above categories. In some relations, the user is not concerned with details procedures and these may be the beginnings of automated reasoning. For instance, in aggregation the user is unaware of the way in which the sub-objects are put together. An example of this is the way that the current version of a section of an English Act of Parliament may be derived from a number of textual amendments in later Acts. Automatic identification of objects and their characteristics is needed in later Acts. Automatic identification of objects and their characteristics is needed to make the selection with the right interconnections for the aggregation. From a database point of view, the identification is provided by the keys in the system [Rossiter & Heather 1988]. Some universally recognized form is necessary to recognize the keys. This enables documents to be addressed and cross-referenced in a natural manner with a standard identification mechanism. Data typing can be used to characterize components of the keys so that documents can be composed from their underlying subsections (subobjects) in a transparent way. The use of natural keys and relations avoids the unnecessarily reductionist methods of early legal retrieval systems.

Elaborate data management systems are needed to provide the high functionality required for structuring, manipulating and maintaining the data with the necessary integrity to provide professional information systems so that end-users may have access transparently to goal-information in a highly organized state. To do this the management system has therefore to recognize inherent relationships in the data to make the necessary hypertext links.

There are often very many, if not an infinite number of, natural connections that can be made. The author or information provider may redefine certain of these based on some expectation of the user's requirements. Alternatively it may be possible to provide some automatic assistance based on predetermined criteria. It is a simple matter to have a dynamic button to pick up references for a glossary or thesaurus where there is a direct connection usually because the item in the text is itself a simple key to the citation. Where there is a partial or a composite key, the system has to have some awareness functionality of what is needed.
Both these methods are limited. The system needs to be able to follow any potential connection under the control of the user. This requires the system to be conscious of where the user is within the document. A very simple example might be given of anaphora when reading from a Hansard CD-ROM, to deal with a sentence beginning with

«As I said in my speech on 28th October to this House...»

the system needs to be aware of the name of the speaker, of whether the current speech is being made in the House of Commons or the House of Lords and of the date of the speech to identify the appropriate year for the 28th October. This necessary awareness required is therefore beyond intelligent hypertext. It also illustrates the practical point that this awareness needs to be a runtime facility. For identifying all possible cross references in advance when only very few of them will ever be required is very inefficient in preprocessing and storage and almost impossible manually.

The law is typical of a number of areas of information where there is a large store of static data which can be kept locally cheaply in video-disk or CD-ROM but where it is essential to be to check the present state against some master version. Take the example the legal question of defining an infringing copy of a piece of software. The current law is to be found in the Copyright, Designs, and Patents Act 1988. When it came into force it confirmed software as having the protection as that of a literary work. Section 27 defined the meaning of ‘infringing copy’ without any special reference to copyright.

However under the Copyright (Computer Programs) Regulations 1992 (Statutory Instrument 1992 No 3233) which came into force on 1st January 1993 the 1988 Act was amended to vary the definition of ‘infringing copy’ from the meaning for other literary works to bring English law in line with the European Directive No. 91/250/EEC (O.J. No L122, 17.5.91, page 42). This situation shows that some awareness and alerting function is necessary to know that some later version is needed. This is only one way in which amendments are prepared in English law. All of which need to be recognizable by the system.

This awareness is now essential in very many areas of business which need continual access to information on changing standards and regulations. This awareness function can be achieved by overlaying another layer of metadata on top of the basic hypertext system. We have to provide this additional layer to simulate a human metamemory for any type of document [Rossiter 1987] and to be reliable as comprehensive as one that like consciousness provides a closure to an open system [Heather 1988].
4. Formal Modelling under Geometric Logic

The logical reasoning obtained with axiomatic methods are subject to the uncertainties of the applicability of the axioms. Constructive mathematics on the other hand attempts to develop logically what works in practice and can perhaps provide the necessary universality for interoperability of heterogeneous data systems with consistency and quality assurance in the real-world. Geometric logic is particularly appropriate for modelling relationships in hyperspace [Heather & Rossiter 1994] for is essentially concerned with links between objects.

From the simple concept of the arrow, formal categories can be constructed of objects with arrow links between them. These provide a natural model for a document. Geometric logic is the formulation between the categories and can therefore represent manipulation of documents in this model of hyperspace. In this model it turns out that linking documents and reasoning are equivalent. This confirms our earlier informal discussion.

Figure 1 shows arrows $K, L$ between categories $A$ and $C$ containing objects $A, B, C, ...$ interrelated by arrows $f, g, ...$. In Figure 1, $K$ assigns from the source object $A$ the target object $K(A)$ to $C$ and from a source arrow $f$ the target arrow $K(f)$ to $g$. The documents and the concepts they contain may be represented by categories $A, B, C, ...$.

**Fig. 1. Functors Compare Categories**

The functor arrow generally represents a hypertext link between documents. The functors can also represent inferences. In geometric logic a deductive system is based on the arrow as a proof:
where $F: A \rightarrow B$ is more than a proof theory entailment. The arrow is the reason why $A$ entails $B$ [Lambek & Scott]. The reasons $F$ and $G$ may be mixture of propositional and predicate logic or even deontic. The inference in the composition $GF$ is then a graph in geometric logic of legal reasoning. At the same time it is calculable through the algebraic form.

Any model needs a philosophical view to be taken of the universe. Hypertext too cannot exist in a philosophical vacuum. Therefore it is perhaps worth mentioning in passing the ontology of this formal model. Reality in the everyday world is made up of rational links as discussed in the first part of this paper. What exists are limits in the sense of geometric logic. A hypermedia is a model of these limits in some cyberspace. These can be represented in this way because of the universal abstract character of category theory.

In general a finite limit in the category $C$ means a limit of a functor $J \rightarrow C$ where $J$ is a finite category. An object in the functor category $C^J$ is a geometric diagram in $C$ of type $J$ which can be representend in general by the cone (together with dual cocone) [Rhydeheard & Burstall 1988].

The nature of proof in category theory should be emphasised. The diagram is a formal diagram. It is a geometric representation equivalent to an expression in algebra. We are in constructive mathematics and the one proof needed is the proof of existence. Therefore so long as it can be shown that the entities belong to formal categories [Freyd 1964], proof up to natural isomorphism is by composition. A formal diagram is in effect a QED. Freyd & Scedrov [1990 p. 29-36] give a formalization of the diagrammatic language.

4.1. Adjointness

Adjointness between two categories

$$F - U : A \rightarrow B$$

has left and right components which specify how an arrow in category $A$ is related to an arrow in category $B$. This is the fundamental concept of implication to be found in geometric logic. The left component is the free functor $F : A \rightarrow B$ and the right component the underlying $U : B \rightarrow A$. $F$ is left adjoint to $U$ and $U$ is right adjoint to $F$. This is a natural bijection between arrows which holds subject to the condition for all objects $A \in C$ and all $B \in B$ such that:
$F(A) \rightarrow B$ implies and is implied by $A \rightarrow U(B)$

Written as a geometric logic inference where the double line indicates the bicontidional (iff);

$$1_A \leq UF \leq 1_B$$

With this condition there are two natural transformations or unit of adjunction:

$$\eta : 1_A \rightarrow UF, \quad c : FU \rightarrow 1_B$$

Adjointness is particularly relevant to hypertext for it represents the concept of relative ordering which is the basis of the connections between documents. $A \leq B$ means $B$ is a later document than $A$ in a hypertext trail. The unit of adjunction is a natural transformation that amounts to an abstraction of the components of the adjointness representing the concepts, objects, message passing, etc. which connect the documents.

By virtue of the adjoint functor theorem [Freyd & Scedrov 1990], left adjoints preserve colimits and right adjoints preserve limits. Colimits are the dual of limits. Both limits and colimits will be examined in more detail.

4.1.1. Adjointness between Text and Image Data

The manipulation of image data based on content and meaning is a burning research topic. Geometric logic shows well the adjointness between textual and graphical information. Both are mapped into the electronic medium as a bit stream.

Multimedia are logical rather than physical based. They are therefore an

![Fig. 2. Adjointness of Electronic Forms](image)
abstract category of a document which may be represented as a textual file or as an image file resulting from input by means of a scanner. Clearly the two forms contain equivalent information although they would appear in quite different electronic forms. This is an important example of adjointness as demonstrated in Fig. 2. TXT (X), GRF(D) and E(2) are categories corresponding respectively to text, graphics and electronic form. Each of these categories is a free functor. TXT (X) maps the alphabet X on to finite strings so a character, x, goes to a string, x → <x>. E (2) is correspondingly composed of strings of zeros and ones. GRF(D) is the much more interesting graphical version which contains all the semiotic significance of the text beyond the mere characters (i.e. punctuation, capitalization, italics). There may be a loss of information from the category GRF(D) to TXT(X).

4.2. Intension-Extension Mapping

The links in hypertext may be at different levels. The mappings representing the links would therefore need to be typed in geometric logic. There is the simple linking between documents like a citation of a label or name (the intension). A more powerful level of connection is within the semantics (the extension). There is also the intension-extension relationship which has been shown by Lawvere [1969] to be composed of adjoint contravariant functors.

The extension level of the abstract document is therefore the same for the three categories of text, graphics and electronic bits. Equality in geo-

Fig. 3. Adjointness in Real-World Semantics
metric logic is provided for by composition. The possible relationships between the three categories of documents at the two levels can therefore all be summed up in a simple geometric formal diagram.

A real-world semantics $S(A)$ can be represented in any of the three forms of graphical, textual and electronic. There will therefore be intension, and extension consisting of contravariant functors between each of the three and $S(A)$ as in the diagram in Fig. 3.

5. **FORMAL CONTEXTUAL SENSITIVITY**

5.1. *Limits, Colimits and Context*

A very fundamental concept that has only been appreciated in the last thirty years is that of *limits* [Mac Lane 1971]. The more straightforward (but technically very important) is the colimit. The colimit of $A$ and $B$ is given by the fullest possible combination of just adding them together to form the sum or disjoint union $A + B$. A partial colimit would be obtained by taking together only certain parts of $A$ and $B$. The parts that are significant when taken together may be provided by the context of a different category $C$. The pushout $A + _CB$ as shown in Fig. 4 then expresses this colimit in context.

![Fig. 4. Diagram of Pushout of $A$ and $B$ over $C$](image)

This is the geometric logic representation of the hypertext link which brings together the documents $A$ and $B$ through the context $C$. Note that this does not give any new information, but only identifies those parts of $A$ and $B$ which are relevant together in the context of $C$.

An example of pushouts can be seen in the geometric logic representation of the remark referred to earlier: "As I said in my speech on 28th October in this House...". The diagram in Fig. 5 shows a pasting together of pushouts in which the result of one pushout *House* is included in turn in another pushout forming $I$. 
Fig. 5. Composition of Pushouts for “As I said in my speech on 28th October to this House…”

New information attained by linking A and B is given by the product limit $A \times B$. This for a context C is the pullback $A \times_c B$ shown in Fig. 6. In general the difference between a limit and colimit is that a limit produces some creative outcome of a link whereas the colimit is a link between standard information.

Fig. 6. Diagram of Pullback of A and B over C

Hypertext is a family of trails and it is important to recognize whether two trails are distinct or whether they merge. Thus there may be two parallel links between the same two documents. The question arises for the hypertext system whether two separate trails arriving at the first document are then merged. For example a legal case may cite a second case more than once during the report but it may be on two quite distinct points of law or even branches of law. Two cases may be connected on a substantive point of law and also quite separately on a point of legal procedure, adjectival law. A document often cites another more than once. Links between two documents in this situation become a limit point in the two trails if
they merge there. However, geometric logic shows that there is a duality of limits also in this instance.

A noequalizer is the situation where there are distinct connections between the same two documents so that separate trails can pass across without merger. With the equalizer any separate trails arriving the first document leave the second document by the same path. An equalizer is a context limit C represented in the diagram of Fig. 7. All trails through A and B are merged through context C which will be shared by both A and B.

Fig. 7. The Equalizer C as a Context Limit on Arrows from A to B

\[ C \rightarrow A \supseteq B \]

The corresponding coequalizer is given by Fig. 8. The context of C is null, that is the limits are independent in thought but from the document perspective there is a context of documents where the two trails exist disjointly. In other words links between documents may be equalizers or coequalizers.

Fig. 8. The Coequalizer C where two Distinct Trails Exist Disjointly

\[ A \supseteq B \rightarrow C \]

Two other special limits are the terminal object and (its dual) the initial object. An object in a category C where there is one and only one arrow from every other object to it is known as the final or terminal object of C. This may be denotes by \( \top \) which is the last object in the trail. Dually (or oppositely) to the final object there may exist a corresponding initial object where there is an arrow from it to every other object in the category. This is \( \bot \), the starting point in the trail and the arrows from it are every potential trail. This has significance for the reasoning and logical content that resides in the hypertext links.

In hypertext the initial and terminal objects may have only a local context. There may not be one single starting point there may be a number of origins for any given trail. Likewise a trail may diverge to more than one finite point.

6. The Hypertext Lattice as a Heyting Algebra

As pointed out by Ted Nelson in his early idea of a hypertext as “non sequential writing with reader-controlled links” [Bolter 1990], links in
hypertext are rarely linear but branch and form a distributive lattice. The internal logic of a lattice is geometric logic which is more general than Boolean logic. The logic of a lattice is well established. It is equivalent to a Heyting algebra. Any Heyting algebra has a fundamental binary operation of implication \( \Rightarrow : A \rightarrow B \). This arrow is commonly written in the form \( A \Rightarrow B \) and this shorthand version will be used here. This implication arrow is defined by the adjunction

\[
\begin{align*}
C \times A \leq B \\
\frac{C \leq A}{C \Rightarrow B}
\end{align*}
\]

\( A \Rightarrow B \) is the largest category whose intersection with \( A \) is contained in \( B \). In hypertext terms if the current document (\( A \)) in its context (\( C \)) precedes document \( B \), then \( B \) is the next document after \( A \) in that context. In terms of concepts rather than documents, the concept may not be represented by a document in existence and from the point of view of a writer be the next document to write.

By the application of this implication we can obtain the more generalized type of negation found in natural systems. Indeed in natural language it is often possible to represent negative concepts in a positive way. This is also true in hypertext where falsity and truth are not simple atomic entities. These are geometric concepts. Truth is given by \( B \Rightarrow T \) and falsity by \( B \Rightarrow \bot \), sometimes written \(- A\).

Truth and falsity are relative to context. In hypertext, \( A \Rightarrow \bot \) is (usually back) in the direction of the initial document, a state of ignorance, whereas \( A \Rightarrow T \) is forward in the direction towards the last document to be viewed in the lattice, the state of enlightenment. Knowledge and ignorance in hypertext are the counterparts of true and false.

The nature of the pseudocomplement the \( A \Rightarrow \bot \) that is not \( A \), may be further understood by substituting the special instance for \( \bot A \) in the definition of the adjunction above. We then get.

\[
\begin{align*}
C \times A \leq \bot \\
\frac{C \leq A \Rightarrow \bot}
\end{align*}
\]

In the real world two negatives do not make a positive. This is familiar in natural language which is against the principle of tertium non datur. The pseudocomplement is so important that natural languages often make it a separate word. For example the concept relevant has the pseudocomplement irrelevant which results in the further concept of not irrelevant. So
not irrelevant is not equivalent to relevant. In fact there is a Heyting ordering:

\[ \mathbf{B} \Rightarrow \perp \leq (\mathbf{B} \Rightarrow \perp) \Rightarrow \perp \leq \mathbf{B} \Rightarrow \perp \]

i.e. irrelevant \leq \text{not irrelevant} \leq \text{relevant}

In hypertext terms, this gives a ranking of the relevancy of the documents in general terms for \( \mathbf{B} \) the next possible document. It is an irrelevant document if it is in the direction of the first document. It is the required next relevant document, if it is in the direction of the final document in the trail. Note when it is not irrelevant. That is, if it is not in the direction of the first document, whether or not it is in the direction of the final document. It is this three level ordering which is the basis of much fuzzy thought and a generalization of fuzzy sets.

In terms of the Heyting algebra, \( \mathbf{C} \Rightarrow \perp \) is another special case of \( \mathbf{A} \Rightarrow \mathbf{B} \). As noted above \( \mathbf{A} \Rightarrow \mathbf{B} \) is itself a concept/document and \( \mathbf{C} \Rightarrow \perp \) is an irrelevant context concept/document. A fundamental feature is that the pseudocomplement \( \mathbf{A} \Rightarrow \perp \) is the largest category disjoint from \( \mathbf{A} \).

7. Awareness in Hypertext

7.1. Contextual Awareness

The earlier discussion on context with pullbacks and pushouts deals with the simpler straightforward type of static and objective contextuality but it is perhaps worth looking at the example previously raised:

"As I said in my speech on 28th October to this House..."

A simple form of contextual awareness can be attained in this example by state of the art database techniques using fields, relations or keys. Thus the information identifying \( \mathbf{I} \), \text{House}, and \text{year} can be anaphorically resolved by reference to meta records in the database system. Fuller details on how this works using keys in a Hansard database is given in [Rossiter & Heather 1988] and [Hudson 1985].

The hypertext system of awareness is one that identifies for the user the next document to see. This is available from the implication \( \mathbf{A} \Rightarrow \mathbf{B} \). Thus awareness is the contravariant natural transformation \( \phi : \mathbf{B} \rightarrow \mathbf{A} \). Awareness in hypertext is therefore the self identification of the document \( \mathbf{B} \) in \( \mathbf{A} \Rightarrow \mathbf{B} \). In Figure 5, it is the document records. The awareness to identify \( \mathbf{I} \) is the Hansard record, the house and the years as given in Fig. 9. This figure
Fig. 9. Awareness to Identify \textit{I} and \textit{House} in “As I said in my speech on 28th October to this House...”

shows how the awareness works. The identity of the speaker \textit{I} is given by \( \phi_3 \), the identification of which house (Lords or Commons) by \( \phi_2 \) and the awareness of the date of the speech from \( \phi_1 \). These can be obtained algebraically. For example \( \phi_2 = \phi_1 \); \( f \) is the meta record giving the house where the speech is given.

7.2. Awareness Model

While the basic principle of hypertext awareness is for that next document \( B \) in \( A \rightarrow B \) to identify itself to the user, the position is complicated by the fact that the user is operating at two levels the intension (represented by the document) and the extension (represented by the meaning). This identification is a precompositional contravariant arrow \( \alpha^\circ : B \rightarrow A \) which is a backward selection from the relevant documents of the document to which they are related.

Hypertext links are really connections between the semantic object in the current document with related semantic objects in the documents to be retrieved. The connection is between objects \( A_1, A_2, \ldots \) in the category \( S(A) \) (that is the meaning of the contents of the document under examination which is \( A \) with objects \( B_1, B_2, \ldots \) in the category \( S(B) \) which are the meanings in the documents to be retrieved \( B \). The identification of the relevant documents depends upon the purpose and intentions of the user. This is a natural transformation \( \eta_A : A \rightarrow S(B) \) as shown in Fig. 10. The awareness is the inverse natural transformation \( \alpha^\circ \).

This is equivalent to analogous reasoning because the inverse natural transformation \( \alpha^\circ \) preserves limits and colimits:
7.3. Relative and Dynamic Contexts

Simple categories may be built up to represent the greatest complexity found in hypertext systems. For instance a concept that emerges from a structure of related documents itself is a diagram as previously indicate and may be used to replace a single object $A$. These can be employed to give hypertext the facility to deal with dynamic, subjective content. In geometric logic this amounts to manipulating more sophisticated structures for diagrams are a more general form of objects and simple categories.

For example the comma category has attracted considerable attention in computing science [Barr & Wells 1990] and can provide general contextuality. The comma category can add structure to an ordinary category by considering the arrows from the point of view of a particular object. Given a category $A$ with a variable object $A$ which may be represented by $A'$ (when we want to distinguish different instances), the arrows $f: A \rightarrow A'$ relative to $C$ are objects in the comma category $A/C$ (sometimes written...
A ↓ C) as shown in Fig. 11. It should be emphasised that the object in the comma category are arrows, the comma category arrows are triangles. For a map of the domain \( A \) and codomain \( A' \) together onto \( C \) specifies \( f: A \rightarrow A' \).

**Fig. 11. Diagram of Comma Category**

\[
\begin{array}{c}
A \\
\downarrow f \\
\triangleright \\
A' \\
\downarrow \\
C
\end{array}
\]

In practice hypertext does not just relate two documents but two documents in their respective categories. Therefore the hypertext link between document \( A \) (the one being viewed) and the next document \( B \) is given in Fig. 12. The functor \( K \) is the hypertext link between the categories when the objects in each category are triangles composed of lower-level arrows. This shows up the dynamical aspects of context.

**Fig. 12. Covariant Functor \( K \) between Comma Categories**

\[
\begin{array}{c}
A \\
\downarrow f \\
\triangle A' \\
\downarrow \\
C
\hline
\rightarrow K
\hline
B \\
\downarrow g \\
\triangle B' \\
\downarrow \\
C'
\end{array}
\]

Figure 13 shows the corresponding contravariant functor \( \alpha^c \) between comma categories.

**Fig. 13. Covariant Functor \( \alpha^c \) between Comma Categories**

\[
\begin{array}{c}
A \\
\downarrow f \\
\triangle A' \\
\downarrow \\
C
\hline
\rightarrow \alpha^c
\hline
B \\
\downarrow g \\
\triangle B' \\
\downarrow \\
C'
\end{array}
\]
Awareness, with relative and dynamic context, is obtained by generalizing from the following relationships shown in Figures 12, 13:

\[ K : A/C \to B/C' \]
\[ \alpha : f \to g \]
\[ \alpha^\circ : B/C' \to A/C \]

The whole collection can be viewed as analogous reasoning thus confirming the equivalence of reasoning and hypertext.

8. Conclusions

The hypermedium has developed into a very sophisticated information system, one that is populated by a variety of distributed hypermedia source material. These heterogeneous materials are pulled together to create a contemporaneous document of the instant based upon the view of the user applied to the inherent structure in the source material.

This view of the user is shaped by the real-world perceptions of the user interacting with the various documents encountered on the way. Because of the power to backtrack and because of inherent branches, it is more than just being shaped by a linear sequence of ideas.

From a set-theoretic perspective, hyperspace is a generalization of a lattice of open sets. For this, set theory or topology would be adequate to deal with ordering in trails but there would be great difficulty in coping with operations across levels and particulary which awareness which has to have some geometric representation of the arrow. The natural transformation \( \alpha^\circ \) is almost impossibly difficult to achieve using inverse functions.

One significant conclusion from the analysis of navigation in a legal hypertext system is that it is akin to legal reasoning.
